Introduction

- VARs are popular tools for forecasting; produce accurate forecasts
- Banbura, Giannone, and Reichlin (2010) showed large VARs work ok
 - Resurgence in use of VARs for forecasting and policy analysis
- Fancier VARs: time-varying parameters, regime switching
 - Good forecasting properties but not necessarily better
 - Competitive to fixed-parameter VARs est.1985+ sample e.g. Aastveit, Carriero, Clark, and Marcellino, 2017
 - Outperforms simple VARs est. 1960+ for inflation and interest rates; mixed-evidence for real variables
 e.g. D'Agostino, Gambetti, and Giannone, 2013; Barnett, Mumtaz, and Theodoridis. 2014: Aastveit et al. 2014
 - Additional computational demands and complexity
- Constant parameter VARs remain popular for forecasting

(日) (同) (三) (三) (三) (○) (○)

Introduction

- Unrestricted long-run forecasts converge to ergodic mean of sample
 - Problematic as at times ergodic mean overlooks external forces (e.g. inflation target; demographic factors) that informs economists' view
 - Poses communication challenge for Monetary Policy, e.g. inflation 3-year out 3.5% from a model estimated with 1960+ data
- Beyond 4 quarters, forecasts increasingly influenced by model's implied steady-state (Clements and Hendry, 1999; Clark and McCracken, 2008)
 - Inflation forecasts 1 to 3 years out likely biased upwards
 - Why not then estimate using a shorter sample that provides more reasonable trend forecast? One possible route
- Some may prefer longer-sample when interest in **forecasts of multiple** variables using a single multivariate model
 - Recent popular papers on VAR (e.g. Banbura et al, 2010; Koop, 2013; Carriero et al, 2015) all focused on longer sample

Introduction

- Survey Long-horizon projections reasonable proxy for underlying trends, such as potential growth, natural rate of unemployment, r-star (e.g. Faust and Wright, 2013)
 - adjust more rapidly in response to changes in underlying fundamentals such as demographic factors not featured in VARs
 - knowledge of inflation target, central bank communications

ELE SQA

In this paper

- Propose a systematic approach to influence forecasts of implied trends from VAR models to values informed from external surveys
- Utilize the technique of relative entropy
 - To tilt the long-horizon VAR forecast of **select** variables towards the long-horizon survey expectations
 - fixed-parameter VARs (short and long sample) and time-Varying VAR
 - Survey of Professional Forecasters (SPF) as it is publicly available
- Implications on forecast accuracy of **all** VAR variables over forecast horizon of interest to monetary policy makers (i.e. 1 to 12 quarters)
- Previous research highlights role of nowcasts to improve multi-horizon forecast accuracy (Kruger et al. 2017; Knotek and Zaman, 2017)
 - also tilt VAR one-quarter ahead forecasts to survey nowcasts

Preview of results

- Improvements in forecast accuracy of VAR forecasts tilted to survey long-run forecasts and nowcasts (hybrid forecast)
 - All models benefit; gains largest for fixed-parameter VAR est. with longer sample and smallest for time-varying VAR
- Time-Varying VAR: significant gains for inflation but small for others
- Constant parameter VAR with longer sample
 - Notable improvements for many variables with biggest gains for price inflation, wage inflation, and interest rates
 - Forecast accuracy for inflation competitive to univariate benchmarks
 - And rivals forecast accuracy from time-varying VAR
- These gains are made possible because our proposal mitigate misspecification issues arising from structural breaks

Related Research

- Incorporating Survey Long-Run Projections into VAR models
 - Wright (2013) uses steady-state VAR of Villani (2009) and sets prior values for steady states informed from Blue Chip survey; stationary VAR and MCMC
 - Modeling in Gaps, i.e. deviation from time-varying trends informed from survey (e.g. Clark and McCracken, 2010; Clark, 2011, Zaman, 2013)
 - Requires the history of survey as long as the estimation sample
- Relative Entropy (RE) to Combine Survey information
 - Applied to forecasting by Robertson, Tallman and Whiteman (2005)
 - Altavilla, Giacomini and Ragusa (2017) tilt segments of term-structure forecasts to survey expectations
 - Kruger, Clark, and Ravazzolo (2017) tilt one-step ahead forecasts from TVP-VAR toward survey nowcasts
- This paper: uses RE to tilt VAR forecasts toward survey Long-Run projections in addition to survey nowcasts

In our examination, we consider following quarterly VAR models:

- Small VAR consisting of five variables (i.e. n=5)
 - Core variables of interest to monetary policy makers: Real GDP growth, CPI Inflation, unemployment rate, federal funds rate
 - Add a financial variable: credit spread (BAA rate 10yr Treasury rate)
 - Several papers on VAR forecasting employ it as a benchmark VAR
- Medium VAR consisting of ten variables (builds on Small VAR by five additional variables; *n*=10)
 - Productivity growth, wage inflation, nonfarm payroll employment growth, real consumption growth, core CPI inflation
 - Shown to be useful in improving forecasts of core variables
 - Forecasts of these additional variables maybe of their own interest
- Time-Varying VAR (real GDP growth, CPI inflation, unemployment rate); along the lines of Primiceri (2005)

The usefulness of Stochastic Volatility

- We also evaluate results of allowing for stochastic volatility (SV) in our Small and Medium VARs
 - past research provides strong evidence of the importance of SV (e.g. Clark, 2011; D'Agostino, Giannone, and Gambetti, 2013)
 - implements the computationally convenient approach of Carriero, Clark, and Marcellino (2016); a phenomenal contribution
 - SV helps significantly improve the calibration of the density forecasts
 - But gains in relative accuracy are marginal because density forecasts from hybrid approach are centered around a more accurate mean
- Presentation focus on results from Small VAR without stochastic volatility

- High-dimensional VARs susceptible to overfitting, estimate using Bayesian methods
 - Employ conjugate Normal-Inverse Wishart prior
 - Prior has computational advantage and competitive forecasting properties (Koop, 2013; Carriero et al, 2015)
 - Allows us to conveniently generate multi-step predictive densities
 - Hyper parameters that govern the tightness of Minnesota and Sum of Coefficients prior are set based on optimizing the marginal likelihood over the pre-forecast evaluation sample

Forecast details

- Forecasts generated recursively with real-time data and evaluated with real-time data (third release); robust to using revised data
- Estimation start 1959.Q4; and 1985.Q1
- Real-time vintages as of SPF date
- Forecasts 1 to 40 quarters ahead but focus on 1 to 12 quarters ahead
- Forecast evaluation samples: 1994.Q1 to 2016.Q4 (and 1994 2006)
- MSE for point forecasts and CRPS metric for density forecasts
- Following Kruger, Clark, and Ravazzolo (2017) statistical significance using Diebold, Mariano and West test using two-sided tests of standard normal
 - HAC variance estimator with lag h-1 truncation parameter; finite sample correction proposed by Harvey et al (1997)

(日) (同) (三) (三) (三) (○) (○)

Methodology: Relative Entropy

- Start with a predictive density **p(Y)** corresponding to an n-dimensional random variable Y generated by our VAR model
- Modify it to obtain a new predictive density **g(Y)** such that it satisfies a given set of moment conditions (e.g. survey forecasts)
- But in doing so minimizes the relative entropy (i.e. Kullback-Liebler Information Criterion) between the two predictive densities; that is g(Y) is as close as possible to the original density p(Y) in the information-criterion sense
- Density g(Y) is essentially a re-weighted original density p(Y)
 - to work there needs to be support in p(Y) for the moment conditions

Methodology: Relative Entropy

- An effective and flexible conditional forecasting method (KCR, 2017)
 - allows to combine both mean condition and the confidence in it
 - an important advantage if the interest is in density forecasts
- In a VAR, conditioning or tilting on some future horizon will influence the forecast starting from the jumping-off point all the way to the tilted horizon
 - e.g. tilt real GDP growth at h=6 then tilting it will impact the forecast trajectory from h=1 to h=5 for all the variables
 - simultaneously tilting on multiple variables result in forecast trajectories that reflect cumulative effect of those conditions
- Easily adapted to any VAR that is able to generate predictive densities

Determining the forecast horizon for tilting

- Natural inclination to combine at some very distant future horizon
- Some macroeconomic variables more persistent than others
 - Unemployment rate very persistent while GDP growth on other extreme
 - Inflation is in between
- Accounting for this is important when combining the forecasts
- **Proposed approach: Informed from the BVAR model estimates** At each forecast origin *t*, retrieve the persistence estimates (i.e. slope parameters), corresponding to variable *i* from equation *i* of the VAR.

$$\rho_{i,t}^{+,BVAR} = \sum_{l=1}^{p} \bar{A}_{i,l}^{(i,i)}$$

where $\bar{A}_{i,l}^{(i,i)}$ is posterior estimate of the slope coefficient of variable *i* in equation *i* of the VAR system.

Determining the forecast horizon for tilting

• The corresponding metric that roughly determines the number of quarters it takes to revert back to BVAR's implied steady state

$$h_{i,t}^{+, BV\!AR} = rac{1}{1-
ho_{i,t}^{+, BV\!AR}}$$

The horizon, $h_{i,t}^*$ at which the survey long-run forecast is combined with the BVAR forecast for variable *i* is set as

$$h_{i,t}^* = \max \{P_t^Q, h_{i,t}^{+,BVAR}\}$$

- P_t^Q provide control to override $h_{i,t}^{+,BVAR}$
- $P_t^Q = 5$ to reflect our preference to have a VAR forecast from h=2 to h=4
- $P_t^Q = 0$ similar results because this choice only binds on real GDP growth

Additional Benefits

- Compare and assess implications on forecast of a range of values
 - Across surveys including with shorter history e.g. Summary of Economic Projections (SEP); median and range as mean and variance restrictions
 - These days policy makers communicate their view of the underlying trend rates
 - Compare how model's forecast of core variables change, Policymaker A vs. B
- Does not require survey history to match estimation sample
 - Could be beneficial for developing and emerging countries
- Interpolate survey forecasts for missing quarters
 - Well-established survey forecasts hard to outperform (e.g. Croushore, 2010)
 - But they cover smaller number of variables and forecast horizons; infrequent
 - SPF and Blue Chip report forecast values for five quarters and 10-year out
- Taylor-rule restriction over the forecast horizon (e.g. Robertson et al, 2005)

Conclusion

- Approach to construct Hybrid forecast consisting of survey nowcast, VAR forecast, and long-run survey forecast
 - Use Relative Entropy; easily adapt to existing VARs
- Meaningful gains in forecast accuracy in all VAR models
 - Gains largest for fixed parameter VARs estimated with longer sample
 - An important practical result; lends credibility to the use of simple VARs for production of forecasts under strict time constraints
- Inflation hybrid forecasts rival univariate benchmark models
 - A useful practical contribution for monetary policy makers
- Hybrid forecasts' accuracy from simple VARs rivals TVP-VARs
- Extent of improvements suggest a post-estimation method to accommodating structural change and moving end points

<ロ> <四> <豆> <豆> <豆> <豆> <豆> <豆> <豆> <豆> <豆</p>

Methodology: Relative Entropy

- Start with a predictive density **p(Y)**
 - *D* draws each with a weight $w_i = 1/D$, where i = 1, ... D
- Modify it to obtain a new predictive density g(Y)
 - such that it satisfies a given set of moment conditions ḡ (e.g. survey forecasts)

 Eg(Y) = ∑^D_{i=1} w^{*}_i p(Y_i) = ḡ
- Minimizes the relative entropy (i.e. Kullback-Liebler Information Criterion)
 - g(Y) as close as possible to p(Y) in the information-criterion sense
 - equivalent to solving for new weights

$$\mathcal{K}(w^*:w) = \sum_{i=1}^{D} w_i^* \log(\frac{w_i^*}{w_i})$$

satisfies the following constraints

$$w_i^* \ge 0, \ \sum_{i=1}^D w_i^* = 1, \ \sum_{i=1}^D w_i^* p(Y_i) = \bar{g}$$

Methodology: Relative Entropy

- Density g(Y) is essentially a re-weighted original density p(Y)
 - to work there needs to be support in p(Y) for the moment conditions
- The solution to the minimization problem using method of Lagrange

$$w_i^* = \frac{w_i \exp(\gamma \ p(Y_i))}{\sum_{i=1}^D w_i \ \exp(\gamma \ p(Y_i))}$$

where γ is the vector of Lagrange multipliers associated with the constraints

• γ can be obtained as a solution to the following minimization problem

$$\gamma = arg \min_{\tilde{\gamma}} \sum_{i=1}^{D} w_i \exp(\hat{\gamma} [p(Y_i) - \bar{g}])$$
